The Simple Dynamics of Public Debt with Productive Public Goods

Pierre-Richard Agénor* and Devrim Yilmaz**

Abstract

This paper analyzes the dynamics of public debt in a simple two-period overlapping generations model of endogenous growth with productive public goods. Alternative fiscal rules are defined, with particular attention devoted to the golden rule. Conditions under which multiple equilibria may emerge under that rule are characterized. The analysis is then extended to consider the case of an endogenous risk premium, an endogenous primary surplus rule, a generalized golden rule, and network externalities. If network effects are sufficiently strong, an increase in public investment may shift the economy from a low-growth equilibrium to a steady state characterized by both higher public debt ratios and higher output growth. This shift may enhance welfare as well. These results illustrate the importance of preserving the allocation of resources to specific types of public investment, even in a context of fiscal retrenchment.

1 Introduction

The global financial crisis has led to massive bailouts of financial institutions and large fiscal stimulus packages in developed and developing countries alike. Combined with a sharp reduction in tax revenues induced by contractions in economic activity, fiscal deficits have reached new highs. According to recent data from the International Monetary Fund (2011), the average deficit for G-7 economies was 8.6 percent in 2010, with 10.3 percent for the United States and 10.2 percent for the United Kingdom. At the same time, a massive buildup of public debt was recorded in these countries. Between 2006 and 2010, general government gross debt as a share of GDP rose from an average of 82.9 percent to 110.4 percent for G-7 economies, and more specifically from 61.1 to 94.4 percent for the United States and 43.1 to 75.5 percent for the United Kingdom. For G-7 economies, public debt is projected to reach an average of 124.8 percent of GDP at end-2016, almost 42 percentage points more than at end-2006.

For the United States alone, prospects are particularly bleak. According to the report of the National Commission on Fiscal Responsibility and Reform (2010), based on current trends revenue will be able to finance only interest payments, Medicare, Medicaid, and Social Security by 2025; every other federal government activity will have to be paid for with borrowed money. The debt-to-GDP ratio could increase to 185 percent of GDP by 2035. According to another report by the Congressional Budget Office released in June 2011, without dramatic cuts to federal health and retirement programs or steep tax increases, the national debt will exceed U.S. GDP by 2021 and reach nearly 200 percent of GDP by 2035.

Not surprisingly, the issue of public debt sustainability has returned to the fore of the policy agenda in many industrial countries. In the largest developing countries, the impact of the crisis on fiscal deficits was not as severe as in advanced economies. Moreover, due to sustained growth, debt ratios actually fell in some of these countries.

---

1 Public debt had started to accumulate well before the crisis in these countries, mostly because of rising spending, but the increase in outlays in the aftermath of the global recession has been rapid and large, as some countries borrowed at record levels. Revenue losses and increases in interest payments were also important factors.

3 In the largest developing countries, the impact of the crisis on fiscal deficits was not as severe as in advanced economies. Moreover, due to sustained growth, debt ratios actually fell in some of these countries.
and that consolidation should also avoid measures, such as cuts in public investment or support for R&D, that would weaken the supply side. This has been a key motivation for emphasizing the need to invest in the provision of productive services, namely infrastructure, in the composition of stimulus packages.\(^4\) In the United States in particular, a growing infrastructure crisis has led to calls for massive investment in roads, bridges, ports (especially on the East Coast, to accommodate bigger container ships from Asia after the expanded Panama Canal opens in 2014) and airports.\(^5\) Investment in infrastructure and spending on maintenance have both declined continuously in the past few years. In the United Kingdom, the government announced in October 2010—shortly after unveiling a fiscal austerity plan that involves drastic cuts in spending—a National Infrastructure Plan, which sets out an ambitious program of public investment on energy, broadband, water, and especially transportation infrastructure.\(^6\)

A natural question that arises therefore is to what extent debt-financed spending on productive public goods “pays for itself”, in the sense of stimulating sufficiently economic growth—without crowding out private investment—to raise revenues and ensure that the debt-output ratio is sustainable, converging to a stable value over time. Fiscal policy in industrial countries faces therefore a double dilemma at the present time: restoring public debt sustainability while making sure that growth is promoted through productive investment. Although less acute, this dilemma is also present in many middle-income countries where, to begin with, stocks of infrastructure assets are much lower than in industrial countries. In Brazil for instance, on April 6, 2010, President Lula da Silva announced a massive plan for public investment in infrastructure (especially new roads, ports, and high-speed trains) dubbed PAC 2, which is aimed at accelerating growth to an average of 5.5 percent a year while preserving

\(^4\) For instance, the National Commission on Fiscal Responsibility and Reform (2010, p. 12) notes that “We should cut red tape and unproductive government spending that hinders job creation and growth. At the same time, we must invest in education, infrastructure, and high-value research and development to help our economy grow, keep us globally competitive, and make it easier for businesses to create jobs.”

\(^5\) In the United States, one-third of the country’s highways—interstates, freeways and major roads—are in poor or mediocre condition, and more than one-quarter of major urban roads, which carry the brunt of national traffic, are in poor condition. Traffic growth has far outpaced highway construction, particularly in major metropolitan areas. See AASHTO (2009) for a thorough discussion.

the government’s goal of generating a budget surplus in the medium term.

The dynamics of public debt and economic growth have been studied in numerous contributions, including Chalk (2000), De la Croix and Michel (2002), Futagami and Shibata (2003), Brauninger (2005), Annichiarico and Giammarioli (2008), Fernandez-Huertas and Vidal (2010), and Michel et al. (2010). Chalk (2000) analyzed the sustainability of bond-financed deficits in a two-period overlapping generations model and shows the conditions under which a growth rate larger than the interest rate is a necessary but not a sufficient condition to ensure the sustainability of a permanent budget deficit. Using also an OLG model, De la Croix and Michel (2002) studied the dynamic effects of the introduction of public debt and derived sustainability conditions. Fernandez-Huertas and Vidal (2010) study fiscal sustainability in an economy where the engine of growth is human capital formation. However, none of these contributions accounts for the provision of productive public goods or the dynamics of public capital. This is important because although public debt accumulation associated with an increase in spending on productive goods subtracts resources from private capital accumulation, exerting a “crowding out” effect, it exerts simultaneously a “crowding in” effect. As long as the growth in public debt (which depends on the share of spending allocated to productive public goods and the share financed by issuing bonds) is not too large, economic growth can be sustained.

A small strand of the literature, which includes Turnovsky (1997), Greiner and Semmler (2000), Ghosh and Mourmouras (2004), Ghosh and Nolan (2005), Greiner (2007, 2011), Futagami et al. (2008), Yakita (2008), Greiner and Flaschel (2010), Arai (2011), and Agénor and Yilmaz (2011), has focused on the dynamics of productive spending, public debt, and growth. This paper contributes to this literature in several ways. First, unlike Ghosh and Nolan (2005), Greiner (2007, 2011), Greiner and Flaschel (2010), and Agénor and Yilmaz (2011), whose analysis dwells on representative agent intertemporal models with a unique balanced growth equilibrium, we consider, as in Yakita (2008) and Arai (2011), an OLG framework. Because the dynamics of consumption are simpler in basic OLG models with log-linear utility, the study of public debt sustainability is somewhat easier—and so is the analytical characterization of multiple equilibria. Second, and in contrast to the latter two papers, the tax rate is not
endogenous. In those models, as in Brauninger (2005), the government fixes its public deficit objective, either as the deficit itself in proportion to output or as the share of the budget deficit to be financed by debt (a criterion consistent with the Maastricht Treaty), and chooses the tax rate residually from the budget constraint.

In our basic framework, the tax rate, the public spending plan and the structure of public deficit financing are exogenous, while the budget deficit is endogenous. As a result, the focus of our analysis is budget realizations, rather than budget objectives. Thus, the sustainability of public debt is discussed in terms of the composition of government spending, rather than a critical level of fiscal deficits. In addition, unlike Yakita (2008) and Arai (2011), we also account for unproductive spending and transfers to households, with the latter creating a direct feedback effect between public debt accumulation, changes in private savings, and private capital formation. Our basic framework yields a dynamic system that is recursive, and thus simpler to analyze than Yakita’s, in particular. We also consider extensions that have not been considered before in the literature, such as an endogenous risk premium and nonlinearities associated with the productivity effects of public capital. The latter is particularly important from the perspective of designing fiscal adjustment programs aimed at promoting growth while ensuring public debt sustainability.

Our main results can be summarized as follows. First, as in some previous studies, we show that the steady-state relationship between output growth and the debt-private capital ratio is unambiguously negative under the golden rule, implying that, with multiple equilibria, the low- (high-) debt equilibrium is associated with a higher (lower) growth rate. However, despite this negative relationship, we also show that an increase in the share of investment in infrastructure has an ambiguous effect on long-run growth. On the one hand, it raises the debt-private capital ratio, which tends to lower growth; on the other, it raises the public-private capital ratio, both directly and indirectly. If the elasticity of output with respect to public capital is sufficiently high, the steady-state growth rate of output will increase. We are able to establish this result because, unlike previous studies, an explicit distinction is made in our model between the elasticities of output with respect to labor and public capital.

Second, we show that with an endogenous risk premium (which rises with the
debt-private capital ratio, to capture default risk), the higher the sensitivity of that premium to the debt-private capital ratio, the more likely it is that multiple equilibria will emerge if the steady-state value of that ratio is less than unity; by contrast, if the debt-private capital ratio is too high, it is more likely that there may be no equilibria. This result is important to understand the (unstable) dynamics of public debt in recent sovereign debt crises in Europe. Third, we introduce network externalities associated with public capital, to capture nonlinearities in its productivity. Until the network is built, public capital has a relatively low (and constant) marginal productivity. Once the basic parts of a network are established, small additional increases in infrastructure investment are associated with strong productivity gains; and beyond another level, the marginal productivity gains induced by additional investments tend to slow down. We find that although the qualitative features of the dynamics of the debt-private capital ratio do not change, a steady-state characterized by high growth and high public debt can now emerge if network effects are sufficiently strong. A large enough increase in the share of output allocated to public investment may therefore shift the economy from a low-growth, low-debt equilibrium to an equilibrium characterized by both higher debt and higher growth. This shift may be welfare-enhancing as well, particularly so if in addition to its productivity effects public capital generates some utility benefits. Again, this result has important implications for the ongoing debate on fiscal consolidation.

The paper continues as follows. Section 2 presents our basic framework, which is based on a two-period overlapping generations (OLG) model with public capital. Section 3 studies the dynamics of the model and the existence of multiple equilibria. Several extensions are considered in Section 4, involving an endogenous risk premium, an endogenous primary surplus rule, a generalized fiscal policy rule, and network effects associated with public capital. The last section of the paper offers some concluding remarks.

2 A Basic Framework

Consider an OLG economy where a single good is produced and individuals live for two periods, adulthood and old age. The good can be either consumed in the period
it is produced or stored to yield capital at the beginning of the following period. Each individual is endowed with one unit of time in adulthood and zero unit in old age. Income consists of both wages in the first period of life and a government transfer, and serves to finance consumption in adulthood and old age. Savings can be held in the form of physical capital or government bonds. Agents have no other endowments, except for an initial stock of physical capital, $K_0^P$ at time $t = 0$, which is held by an initial generation of retirees. There are no altruistically-motivated intergenerational bequests, implying that Ricardian equivalence does not hold.\footnote{In fact, even with bequests, Ricardian equivalence would not hold here, due to the presence (as discussed later) of distortionary income taxation.}

Population is constant. In addition to individuals, the economy is populated by firms and an infinitely-lived government. Firms produce goods using private capital, labor, and public capital as inputs. The government invests in a productive good and spends on some unproductive services, including transfers to households. It provides its services free of charge. It taxes only the wage income of adults and issues one-period bonds to finance its deficit. All markets clear in equilibrium.

\subsection{Households}

Expected lifetime utility at the beginning of period $t$ is

$$U_t = \ln c_t^t + \ln \frac{c_{t+1}^t}{1 + \rho}$$

where $c_{t+j}^i$ denotes consumption of generation $i$ individuals at date $t + j$ and $\rho > 0$ the discount rate.

Period-specific budget constraints are given by

$$c_t^t + s_t = (1 - \tau)w_t + x_t,$$

$$c_{t+1}^t = (1 + r_{t+1})s_t,$$

where $w_t$ is the wage rate, $\tau \in (0, 1)$ the tax rate, $x_t$ a government transfer (which the household takes as given when solving its optimization problem), $r_{t+1}$ the rental rate.
of private capital, and $s_t$ saving. To simplify matters, transfers and interest income of old agents are not taxed.8

The household’s consolidated budget constraint is

$$c_t^i + \frac{c_{t+1}^i}{1 + r_{t+1}} = (1 - \tau)w_t + x_t. \quad (4)$$

### 2.2 Firms

There is a continuum of identical firms, indexed by $i \in (0, 1)$. They produce a single nonstorable good, which is used either for consumption or investment. Production requires the use of private inputs, labor and private capital (which firms rent from the currently old agents), and public capital.

The production function of firm $i$ takes the form

$$Y_t^i = (K_t^P)^\alpha (K_t^I)^\eta (N_t^i)^\beta (K_t^{P,i})^{1 - \beta}, \quad (5)$$

where $K_t^{P,i}$ denotes the firm-specific stock of capital, $K_t^P = \int_0^1 K_t^{P,i}di$ the aggregate private capital stock, $K_t^I$ the stock of public capital, $N_t^i$ the number of workers employed by firm $i$, $\alpha, \eta > 0$, and $\beta \in (0, 1)$. Thus, production exhibits constant returns to scale in firm-specific inputs, $N_t^i$ and $K_t^{P,i}$. Public capital in infrastructure is exogenous to each firm’s production process and affects all individual producers in the same way. There is also an Arrow-Romer type externality associated with aggregate private capital. The magnitudes of these externalities are measured by $\alpha$ and $\eta$, respectively. In line with much of the empirical evidence reviewed in Bom and Ligthart (2014), based on linear, single-equation estimation, we impose $\alpha < 1$.

Markets for both private capital and labor are competitive. Each firm’s objective is to maximize profits, $\Pi_t^i$, with respect to labor services and private capital, taking $K_t^I$ and $K_t^P$ as given:

$$\max_{N_t^i, K_t^{P,i}} \Pi_t^i = Y_t^i - (r_t + \delta)K_t^{P,i} - w_tN_t^i,$$

where $r_t$ is the rental rate of private capital and $\delta \in (0, 1)$ is the depreciation rate.

---

8For simplicity, we also abstract from government transfers to the old generation (as in Annichiarico and Giammarioli (2008) or Michel et al. (2010) for instance) and issues associated with social security.
Profit maximization yields, in a symmetric equilibrium,

\[ w_t = \beta Y_t / \bar{N}, \quad r_t + \delta = (1 - \beta) Y_t / K_t^P. \]  

(6)

where \( \bar{N} = \int_0^1 N_i d\bar{N} \) is total population, which is normalized to unity in what follows. The second expression equates the user cost of capital to the gross marginal physical product of private capital.

Because the number of firms is normalized to 1, aggregate output is given by

\[ Y_t = \int_0^1 Y^i_t d\bar{N} = (k_t^I)^\alpha (K_t^P)^{1+\alpha-\beta+\eta}, \]  

(7)

where \( k_t^I = K_t^I / K_t^P \) is the public-private capital ratio. To ensure balanced growth (linearity of output in the private capital stock) requires the following assumption:9

**Assumption 1:** \( \eta = \beta - \alpha. \)

Under Assumption 1, (7) yields aggregate output as10

\[ Y_t = (k_t^I)^\alpha K_t^P. \]  

(8)

### 2.3 Government

The government taxes adults at the constant rate \( \tau \) and spends a total of \( G_t^I \) on productive public goods and \( G_t^U \) on other (unproductive) items, including transfers. The government budget constraint is

\[ B_{t+1} = (1 + i_t) B_t + G_t^I + G_t^U - \tau w_t, \]  

(9)

where \( i_t \) is the gross rate of return on government bonds. The expression \( G_t^I + G_t^U - \tau w_t \) represents therefore the primary budget deficit.

Shares of spending are assumed initially to be constant fractions of revenues:

\[ G_t^h = v_h \tau w_t, \quad h = I, U \]  

(10)

9 With \( \beta \) in the range of 0.6-0.7, and \( \alpha \) in the range of 0.1-0.2, this gives a value of \( \eta \) in the range of 0.4-0.6. If \( \eta = 0 \) then \( \alpha = \beta \), as in various contributions, stemming from Barro (1990). However, this case is somewhat misleading, as discussed later. Note also that there is a scale effect in production, which can be eliminated by specifying the Arrow-Romer externality in terms of the ratio of the aggregate private capital stock to the size of the population.

10 An aggregate production function similar to (8) can be derived in the presence of congestion effects; see for instance Agénor (2009).
where \( v_h \in (0, 1) \). Combining (9) and (10) therefore yields

\[
B_{t+1} = (1 + i_t)B_t - [1 - (v_I + v_U)] \tau w_t. \tag{11}
\]

Thus, with a primary balance rule, \( v_I + v_U = 1 \), all taxes are spent on non-interest outlays, and debt remains constant at zero if \( B_0 = 0 \); otherwise, it grows autonomously as long as \( i_t > 0 \). By contrast, with a primary surplus rule, \( v_I + v_U < 1 \), the government uses a fraction of its tax revenues to service its debt, and debt will fall over time if the interest rate is not too high.

Assuming full depreciation, the law of motion of the public capital stock in infrastructure is given by

\[
K_{t+1}^I - G_t^I. \tag{12}
\]

### 2.4 Market-Clearing and Equilibrium

The market-clearing condition requires private savings be equal to tomorrow’s stock of physical assets plus the stock of government bonds:

\[
K_{t+1}^P + B_{t+1} = \bar{N}s_t. \tag{13}
\]

On the basis of these equations, the following definitions can be provided.

**Definition 1:** A competitive equilibrium in this economy is a sequence of prices \( \{w_t, r_t, i_t\}_{t=0}^\infty \), consumption and savings \( \{c_t^I, c_{t+1}^I, s_t\}_{t=0}^\infty \), public and private capital stocks \( \{K_t^P, K_{t+1}^P\}_{t=0}^\infty \), government debt \( \{B_t, B_{t+1}\}_{t=0}^\infty \), a constant tax rate \( \tau \) and constant spending shares \( v_I, v_U \), such that, given the initial capital stocks \( K_0^P \) and \( K_0^I > 0 \) and the initial public debt \( B_0 > 0 \), individuals maximize utility, firms maximize profits, and the product market clears.

**Definition 2:** A balanced growth equilibrium is a competitive equilibrium in which \( c_t^I, c_{t+1}^I, w_t, Y_t, K_t^P, K_{t+1}^I, \) and \( B_t \) all grow at the constant rate \( 1 + \gamma \) and the rate of return on private capital \( r_t \) and the interest rate on government bonds \( i_t \) are both constant over time.

\[11\] A more general specification would be to assume that the production of public capital requires combining both the spending flow on productive goods and the existing stock of public capital, so that \( K_{t+1}^I = (G_t^I)^\mu (K_t^I)^{1-\mu} \), with \( \mu \in (0, 1) \). Our results would remain qualitatively similar. Note also that we do not consider the issue of efficiency of public investment, which could be captured, as in Agénor (2010) for instance, by multiplying \( G_t^I \) in (12) by a parameter that takes a value lower than unity.
By implication, the public debt-private capital ratio and the public-private capital ratio are both constant in equilibrium.

In what follows transfers to each individual are assumed to be given by a fraction of unproductive spending per capita; thus, $x_t = \chi G_t^U / \bar{N}$, where $\chi \in (0, 1)$. Using this assumption, and given the normalization $\bar{N} = 1$, it is straightforward to establish that optimal savings are given by

$$s_t = \sigma [(1 - \tau) + u_t \tau \chi] \beta Y_t,$$  \hspace{1cm} (14)

where $\sigma = 1/(2 + \rho) < 1$ is the individual, before-tax savings rate. Thus, given the log-linear utility function used in (1), the savings rate does not depend on the rental rate of capital, $r_{t+1}$.

Assuming that physical and financial assets are perfect substitutes implies the no arbitrage condition $1 + r_t = 1 + i_t$. Thus, using (6) and (8), and assuming full depreciation of private capital as well ($\delta = 1$), yields

$$i_t = \frac{(1 - \beta)Y_t}{K_t^p} - 1 = (1 - \beta)(k_t^h)^\alpha - 1.$$  \hspace{1cm} (15)

Thus, changes in the interest rate on government debt are endogenously determined through changes in the public-private capital ratio. As shown next, this link creates interdependence between the dynamics of public debt and the stocks of public and private capital, but in a transformed system with stationary variables this occurs in a recursive manner.

3 Dynamics and Fiscal Rules

We begin by deriving the dynamics of the debt-private capital ratio and the growth rate of output. Sustainability of fiscal policy is defined in the process, in relation to the existence of a balanced growth equilibrium. We then consider three alternative fiscal rules (a primary balance rule, a primary surplus rule, and a golden rule) and examine the conditions under which multiple equilibria, all characterized by a positive and constant public debt-private capital ratio, may emerge.
3.1 Debt and Growth Dynamics

To analyze the dynamics of the economy, begin by substituting (10) in (12) and use (6) to give

$$K_{t+1}^I = v_I \tau \beta Y_t.$$  

(16)

Substituting (6), (11) and (14) in (13) yields

$$K_{t+1}^P = \Lambda_1 Y_t - (1 + i_t)B_t,$$  

(17)

where

$$\Lambda_1 = \{\sigma[(1 - \tau) + v_U \tau \chi] + [1 - (v_I + v_U)]\tau\beta,$$  

(18)

is the aggregate, after-tax savings rate, whose sign depends on the fiscal rule in place.

Using (8) and (15), and with $b_t = B_t/K_t^P$ defined as the public debt-private capital ratio, equation (17) can be written as

$$\frac{K_{t+1}^P}{K_t^P} = \Lambda_1(k_t^I)^\alpha - (1 - \beta)(k_t^I)^\alpha b_t.$$  

(19)

Similarly, from (8) and (16),

$$\frac{K_{t+1}^I}{K_t^I} = v_I \tau \beta(\frac{Y_t}{K_t^I}) = v_I \tau \beta(k_t^I)^{\alpha - 1}. $$  

(20)

Dividing (20) by (19) gives

$$k_{t+1}^I = \frac{v_I \tau \beta}{\Lambda_1 - (1 - \beta)b_t}.$$  

(21)

Equation (21) determines the dynamics of the public-private capital ratio as a function solely of the debt-private capital ratio. As implied by (18), with a primary balance rule, $\Lambda_1$ is always positive; in general, however, this is not the case. For (21) to yield a positive value of $k_t^I$ in a steady state with positive debt, the following necessary (although not sufficient) restriction is imposed:

**Assumption 2**: $\Lambda_1 > 0$.

\[ \text{It can easily be established that, if as noted earlier public capital accumulation is specified as } \]
\[ K_{t+1}^I = (G_t^I)^\mu(K_t^I)^{1-\mu}, \text{ with } \mu \in (0,1) \text{ instead of (12), } k_{t+1}^I \text{ in (21) would also depend on } k_t^I. \text{ However, the system would remain recursive.} \]
Because $\Lambda_1$ depends on how government spending is allocated, whether Assumption 2 is satisfied or not depends on the nature of the fiscal rule, as discussed later.

Now, to determine the dynamics of public debt, note that equation (11) can be written as, using (6),

$$\frac{B_{t+1}}{B_t} = 1 + i_t - [1 - (v_t + v_U)]\tau \beta \left( \frac{Y_t}{K_t^P} \right) \left( \frac{K_t^P}{B_t} \right),$$

that is, using (8) and (15),

$$\frac{B_{t+1}}{B_t} = [(1 - \beta) - \Lambda_2 t^{-1}] (k_t^f)^\alpha,$$  \hspace{1cm} (22)

where

$$\Lambda_2 = [1 - (v_t + v_U)]\tau \beta.$$  \hspace{1cm} (23)

Dividing (22) by (19) gives

$$b_{t+1} = \frac{[(1 - \beta) - \Lambda_2 t^{-1}] b_t}{\Lambda_1 - (1 - \beta) b_t},$$

or equivalently

$$b_{t+1} = \frac{(1 - \beta) b_t - \Lambda_2}{\Lambda_1 - (1 - \beta) b_t} = \Phi(b_t),$$  \hspace{1cm} (24)

from which it can be established that$^{13}$

$$\Phi'(b_t) = \frac{(1 - \beta)(\Lambda_1 - \Lambda_2)}{[\Lambda_1 - (1 - \beta) b_t]^2}, \quad \Phi''(b_t) = \frac{2(1 - \beta)\Phi'(b_t)}{\Lambda_1 - (1 - \beta) b_t}.$$

From the definitions of $\Lambda_1$ and $\Lambda_2$ in (18) and (23), it can be established that $\Lambda_1 - \Lambda_2 > 0$. Thus, $\Phi(b_t) > 0$. Given Assumption 2, to ensure that the public-private capital ratio is positive requires that the debt-private capital ratio be less than $\Lambda_1/(1 - \beta)$. If so then $\Phi''(b_t)$ is also positive, which implies that the transition curve $\Phi(b_t)$ is convex, as illustrated in Figure 1.$^{14}$

The model consists therefore of (21) and (24). It is recursive: equation (24) determines the evolution of $b_t$, which can be substituted in (21) to determine the evolution of $k_t^f$. The fundamental reason for this property, as can be inferred from (8), (19), and

$^{13}$Note that, because (19) and (22) are both linear in $(k_t^f)^\alpha$, the parameter $\alpha$ has no effect on the short-run dynamics of the debt-private capital ratio.

$^{14}$The figure assumes that $-\Lambda_2/\Lambda_1 > 0$, which turns out to be the case for some of the fiscal rules considered later. Note that the transition curve becomes steeper as $-\Lambda_2/\Lambda_1$ rises.
(22), is that both the private capital stock and the stock of public debt are linear in the output-capital ratio.

We can now provide a definition of fiscal sustainability.\textsuperscript{15}

**Definition 3:** A fiscal policy rule defined by a vector \((v_1, v_U, \chi, \tau)\) of budgetary parameters is sustainable if, for given structural parameters \((\alpha, \beta, \sigma)\) and an initial value \(b_0 > 0\), it is associated with a balanced growth equilibrium with \(\tilde{b} > 0\).

Put differently, and by implication of Definition 2, a fiscal policy rule is sustainable if there exists a balanced growth path in the system, because in that case the debt-private capital ratio (given an initial level \(b_0\)) always converges to some positive, finite level in the long run.\textsuperscript{16} Note that this definition does not exclude the possibility of multiple equilibrium growth paths.

Now, to determine the economy’s balanced growth path, write equation (8) for \(t+1\), so that

\[ Y_{t+1} = (k_{t+1}^L)^\alpha K_{t+1}^P, \]

or equivalently, using (17),

\[ Y_{t+1} = (k_{t+1}^L)^\alpha [\Lambda_1 Y_t - (1 + i_t) B_t]. \]

Substituting (15) in this expression yields

\[ Y_{t+1} = (k_{t+1}^L)^\alpha [\Lambda_1 - (1 - \beta)b_t] Y_t, \]

that is, using (21),

\[ 1 + \gamma_{t+1} = \frac{Y_{t+1}}{Y_t} = (v_1 \tau \beta)^\alpha [\Lambda_1 - (1 - \beta)b_t]^{1-\alpha}, \]

which implies a negative relationship between the debt-private capital ratio and the growth rate of output. On the one hand, an increase in \(b_t\) raises the public-private

\textsuperscript{15}In the standard definition of fiscal (or debt) sustainability, a fiscal policy is said to be sustainable if the present value of future primary surpluses equals the current level of debt (see, for instance, Collignon (2012)). Put differently, the budget must be balanced in present value terms to rule out Ponzi games. The definition provided here is broader and in line with the recent analytical literature; see for instance, Yakita (2008). Moreover, in a model as simple as the one considered here (with, in particular, log-linear utility), it encompasses the no-Ponzi game condition.

\textsuperscript{16}In general, \(\tilde{b}\) can be either positive or negative. However, from an economic point of view a positive value of government debt is more realistic.
capital ratio, which tends to promote growth; on the other, it lowers the rate of private
capital accumulation, which tends to hamper growth. Given our parameter assump-
tions (namely, \( \alpha < 1 \)), and the linearity of the aggregate production function in the
private capital stock, the crowding-out effect dominates the crowding-in effect and the
net impact on growth of higher debt is (all things equal, specifically for \( v_I \) given) always
negative.

Setting \( b_{t+1} = b_t \) in (24) implies that the steady-state debt-private capital ratio is
the solution of the quadratic equation

\[
(1 - \beta)\tilde{b}^2 - [\Lambda_1 - (1 - \beta)]\tilde{b} - \Lambda_2 = 0, \tag{26}
\]

where \( \Lambda_1 - (1 - \beta) \leq 0 \) in general. From (21), the steady-state public-private capital
ratio is given by

\[
\tilde{k}^l = \frac{v_I\tau\beta}{\Lambda_1 - (1 - \beta)\tilde{b}}, \tag{27}
\]

which describes a convex relationship again between \( \tilde{k}^l \) and \( \tilde{b} \). Similarly, from (25) the
equilibrium growth rate of output is

\[
1 + \gamma = (v_I\tau\beta)^a[\Lambda_1 - (1 - \beta)\tilde{b}]^{1-a}. \tag{28}
\]

Depending on the values of \( \Lambda_1 \) and \( \Lambda_2 \), the model may exhibit no equilibrium, a
single equilibrium, or two equilibria. And given that both \( \Lambda_1 \) and \( \Lambda_2 \) depend on the
fiscal policy rule, we need now to consider alternative specifications of these rules.

### 3.2 Alternative Fiscal Rules

With a primary balance rule, \( v_I + v_U = 1 \); from (18) and (23), \( \Lambda_1 = \sigma[(1 - \tau) + v_U\tau\chi] \beta > 0 \) and \( \Lambda_2 = 0 \). Thus, Assumption 2 is always satisfied. Ignoring the trivial solution
\( \tilde{b} = 0 \), equation (26) boils down to\(^{17}\)

\[
\tilde{b} = \frac{\Lambda_1 - (1 - \beta)}{1 - \beta} = \frac{\Lambda_1}{1 - \beta} - 1, \tag{29}
\]

which is positive as long as \( \Lambda_1 - (1 - \beta) > 0 \). In turn, this condition requires \((1 - \tau) + v_U\tau\chi > (1 - \beta)/\sigma\beta\), or equivalently

\[
v_I < v_f \bigg|_{v_I+v_U=1} = 1 + (\tau\chi)^{-1}\left\{1 - \tau - \frac{1 - \beta}{\sigma\beta}\right\}. \]

\(^{17}\)With a primary balance rule, the origin of the transition curve is at 0 in Figure 1.
With \( \tilde{b} \) given by (29), equations (27) and (28) imply that the public-private capital ratio and the growth rate are given by \( \tilde{k}' = v_I \tau \beta / (1 - \beta) \), and \( 1 + \gamma = (v_I \tau \beta)^\alpha (1 - \beta)^{1 - \alpha} \), which are always positive. From (15), \( 1 + \hat{\imath} = 1 + \gamma \), or equivalently the rate of return to capital must be equal to the growth rate of output to ensure that the debt-private capital (or, equivalently, the debt-output) ratio does not explode. These results can be summarized in the following proposition.

**Proposition 1.** With a primary balance rule, and positive transfers to households, a steady-state equilibrium with positive debt, a positive public-private capital ratio, and positive growth exists if the share of government spending allocated to investment is not too large.

Intuitively, with a primary balance rule, interest payments alone drive the growth in public debt. However, the no-arbitrage condition implies a positive relationship between the interest rate on government bonds and the public-private capital ratio; if that ratio grows too fast, because the fraction of resources allocated to investment in infrastructure is too high, public debt will grow too fast compared to private capital and output. Convergence cannot be achieved.

With a primary surplus rule, \( v_I + v_U < 1 \), and from (18), (23) and Assumption 1, \( \Lambda_1, \Lambda_2 > 0 \). In fact, regardless of the sign of \( \Lambda_1 - (1 - \beta) \), equation (26) yields one positive and one negative solution for \( \tilde{b} \). There are no multiple equilibria in that case. Moreover, it can be verified that the admissible equilibrium is always unstable. Intuitively, if the initial value of debt is lower than the (unique) equilibrium value, the policy rule drives that debt to zero in finite time. Conversely, if public debt is initially higher than its equilibrium value, the policy is unable to tame the unstable dynamics associated with interest payments; as a result, the debt-public capital ratio grows without bounds.

With an (interest-inclusive) golden rule, \( v_U = 1 \), all public investment and interest payments are financed by borrowing, and \( \Lambda_1 = \{\sigma[(1 - \tau) + \tau \chi] - v_I \tau \} \beta \geq 0 \), \( \Lambda_2 = \frac{\Delta}{2(1 - \beta)} \)...

---

\(^{18}\)This is a direct implication of Descartes’ rule of signs, according to which the number of positive real roots of a polynomial is bounded by the number of changes in sign of the sequence of its coefficients. The discriminant of (26) is \( \Delta = [\Lambda_1 - (1 - \beta)]^2 + 4(1 - \beta)\Lambda_2 \), which is always positive. The positive solution is \( \Lambda_1 - (1 - \beta) + \sqrt{\Lambda_1} \). The transition curve \( \Phi(b) \) intersects the 45-degree line only once, from below.
\[-v_I \tau \beta < 0. \tag{20, 21}\]

However, the nature of the equilibria depends on the sign of \(\Lambda_1 - (1 - \beta)\). If \(\Lambda_1 - (1 - \beta) > 0\) (a necessary condition for which is \(\Lambda_1 > 0\), as noted in Assumption 2), equation (26) can yield zero, one, or two positive solutions for \(\tilde{b}\). By contrast, with \(\Lambda_1 - (1 - \beta) < 0\), there are no positive solutions to (26).\tag{22} Intuitively, in that case even if the aggregate savings rate is positive (\(\Lambda_1 > 0\)), it is not large enough to ensure positive private capital accumulation because the fraction of the economy’s savings claimed by the government (through the accumulation of public debt) is too high.

The condition for \(\Lambda_1 - (1 - \beta) > 0\) is now \(\sigma[(1 - \tau) + \tau \chi] - v_I \tau > (1 - \beta)/\beta\), or equivalently

\[
v_I < v_I^1_{v_U = 1} = \tau^{-1} \left\{ \sigma[(1 - \tau) + \tau \chi] - \frac{1 - \beta}{\beta} \right\}.
\]

This restriction on \(v_I\) is thus necessary, but not sufficient, to generate multiple equilibria. To do so there is a second critical value of \(v_I\) below which multiple equilibria can emerge, determined by \(\Lambda_1 = (1 - \beta) + 2\sqrt{-\Lambda_2(1 - \beta)}\), or equivalently

\[
\{\sigma[(1 - \tau) + \tau \chi] - v_I \tau}\beta - (1 - \beta) - 2\sqrt{v_I \tau \beta(1 - \beta)} = 0. \tag{30}
\]

This expression cannot be solved analytically for \(v_I\). Let \(v_I^2_{v_U = 1}\) denote the threshold value of \(v_I\) implied by (30); then it must be that \(v_I^2_{v_U = 1} < v_I^1_{v_U = 1}\). This is proved in a simple manner in Figure 2. Let \(h(v_I) = \{\sigma[(1 - \tau) + \tau \chi] - v_I \tau}\}\beta; it is linear in \(v_I\), with a negative slope \(h' = -\tau \beta\). Let also \(g(v_I) = (1 - \beta) + 2\sqrt{v_I \tau \beta(1 - \beta)}\); it is an increasing, concave function of \(v_I\), with \(g(0) = 1 - \beta\). The critical value \(v_I^1_{v_U = 1}\) is determined at the intersection of \(h(v_I)\) with the line \(1 - \beta\), at Point A, whereas the critical value \(v_I^2_{v_U = 1}\) is determined at the intersection of \(h(v_I)\) and \(g(v_I)\), at Point

\footnote{Note that in that case, as implied by (10), investment spending is still defined in terms of a fraction of tax revenues. As a share of output, government investment is simply \(\tau v_I\).}

\footnote{We consider an interest-inclusive golden rule in the benchmark case on the ground that if investment today is going to benefit future generations, then the whole burden of repaying the debt, which includes interest payments, should be borne by future generations as well. In the next section a more general rule, which considers only partial bond financing of interest payments, is considered.}

\footnote{More precisely, the existence and the number of equilibria depends on the sign of \(\Delta = [\Lambda_1 - (1 - \beta)]^2 + 4(1 - \beta)\Lambda_2\), which is in general ambiguous. If \(\Delta > 0\), there are two positive values of \(\tilde{b}\) that will satisfy (26), whereas with \(\Delta = 0\), the equilibrium is unique. With \(\Delta < 0\), there is no equilibrium with real values. After some manipulations, the necessary condition for the existence of multiple equilibria can be expressed as \(\Lambda_1 > (1 - \beta) + 2[-\Lambda_2(1 - \beta)]^{0.5}\). With \(\Lambda_1 - (1 - \beta) < 0\), this condition cannot be fulfilled.}
For \( v_I \in (v_I^C|_{v_U=1}^2, v_I^C|_{v_U=1}^1) \) there is no admissible equilibrium (consistent with Definitions 1-3), whereas for \( v_I = v_I^C|_{v_U=1}^2 \) there is a single equilibrium. In Figure 1, this corresponds to the point at which the transition curve \( \Phi(b_t) \) is tangent to the 45-degree line, at Point A; in Figure 2, this corresponds to Point B, where \( h(v_I) \) and \( g(v_I) \) intersect. For \( v_I < v_I^C|_{v_U=1}^2 \) there are multiple equilibria.\(^{24}\)

These results can be summarized as follows.

**Proposition 2.** With a golden rule, there are no equilibria with a non-negative steady-state value of the public debt-private capital ratio if \( v_I \in (v_I^C|_{v_U=1}^2, v_I^C|_{v_U=1}^1) \); single equilibrium if \( v_I = v_I^C|_{v_U=1}^1 \), and multiple equilibria if \( v_I < v_I^C|_{v_U=1}^2 < v_I^C|_{v_U=1}^1 \).

In Figure 2 we also compare the threshold levels of the investment share under the primary balance and the golden rules. Let \( z(v_I) = \sigma[(1-\tau) + (1-v_I)\tau\chi]\beta - (1-\beta) \), which is also linear in \( v_I \), with a slope \( z' = -\sigma\tau\chi\beta \) and \( z(0) = h(0) \). Because \( |z'| < |h'| \), the threshold value of the investment share for an equilibrium with a positive steady-state solution of the debt-private capital ratio is unambiguously higher with a primary balance rule. This is quite intuitive.

The possibility of multiple (nontrivial) equilibria in the case of the golden rule under the condition \( \Lambda_1 - (1-\beta) > 0 \), is illustrated in Figure 1. If \( v_I \) is too high (that is, \( v_I > v_I^C|_{v_U=1}^1 \)), the transition curve \( \Phi(b_t) \) is located entirely above the 45-degree line and there is no equilibrium. Put differently, if the golden rule calls for investing a fraction \( \tau v_I \) of output that is too large, the economy cannot reach a steady state, because debt grows faster than the stock of public capital, which implies that the debt-private capital ratio explodes. An overambitious, debt-financed program of public capital accumulation is not sustainable.

The figure also shows that there is a single equilibrium at Point A, and two equilibria at Points B and \( B' \). Inspection of these equilibria, together with (27) and (28), yields the following results.

\(^{23}\)Figure 2 assumes that \( h(0) = \sigma[(1-\tau) + \tau\chi]\beta > 1-\beta \). This condition is satisfied for a large range of reasonable values for the underlying parameters.

\(^{24}\)A *general borrowing “rule,”* in which the government borrows to finance either higher investment or unproductive spending, could also be defined by setting \( v_I + v_U > 1 \). However, it is easy to verify that the nature of the solution to the model (namely, the conditions for generating multiple equilibria, this time in terms of \( v_I + v_U \)) is qualitatively similar to what is obtained under the golden rule.
Proposition 3. When multiple steady-state equilibria exist, the equilibrium with the smaller (larger) public debt-private capital ratio is stable (unstable) and is associated with a lower (larger) public-private capital ratio and a higher (lower) growth rate of output.

The negative correlation between the debt-private capital ratio and the growth rate of output, which can be directly inferred from (28), results from the fact that the crowding-out effect of public debt always dominates the productivity effect of public capital.\textsuperscript{25} By implication of Proposition 3, the economy can attain the high steady state only if it starts there. If the initial debt-private capital ratio is at $b_0^1$ for instance, or at any point located below $b_M$ (corresponding to Point $B'$), the economy will converge over time toward the low-debt, high-growth equilibrium $B$, which is characterized by equality between the growth rates of both capital stocks, output, and public debt. By contrast, if the economy starts at any point located above $b_M$, such as $b_0^2$, it will move over time away from the high-debt, low-growth equilibrium. The growth in public debt always exceeds the growth in the private capital stock, implying that their ratio increases continuously. In that sense, the fiscal policy is unsustainable; public investment must be cut sufficiently to ensure that the transition curve shifts down, in such a way that it intersects the 45-degree line to the right of point $C$; if so, the economy will begin to converge toward the low-debt, high-growth equilibrium. Put differently, if the initial debt is not too high (below $b_M$), the existing fiscal policy is sustainable, and movements along the transition curve will lead to a low-debt steady state; if the initial debt is too high (above $b_M$), a policy change, involving a downward shift in the transition curve, is required to make the fiscal stance sustainable.\textsuperscript{26} The

\textsuperscript{25}In turn, as noted earlier, this is due to the linearity of the production function (8) with respect to private capital and the fact that $\alpha < 1$. If there is crowding out, the effect of the reduction in the private capital stock always dominates the effect of an increase in the public capital stock—despite the fact that the former magnifies the increase in the public-private capital ratio.

\textsuperscript{26}Note that with the general borrowing “rule” referred to earlier, according to which the government issues debt to finance both investment and unproductive spending ($v_I + v_U > 1$), the adjustment needed to ensure sustainability could involve cuts only in the latter component. However, if the initial debt ratio is well above $b_M$, cuts in both types of outlays may be inevitable. Alternatively, the initial debt level could be cut (at $t = 0^+$) to a level below $b_M$ either through debt cancellation, debt writedown, or unilateral default (assuming that the latter incurs only temporary costs). In fact, if the incompressible level of public expenditure related to both current spending (on schools, the police, and courts for instance) and capital investment is high, a combination of expenditure reduction and debt cancelation may well be necessary to ensure that the fiscal adjustment is large enough to guarantee

19
value $b_M$ is therefore the maximum initial debt-private capital ratio consistent with sustainability.

Another way to illustrate the possibility of multiple equilibrium values in the public debt-private capital ratio under the golden rule is as follows. Defining $p(\bar{b}) = (1 - \beta)\bar{b}^2$ and $q(\bar{b}, v_I) = [\Lambda_1 - (1 - \beta)]\bar{b} + \Lambda_2$, equation (26) can be rewritten as

$$p(\bar{b}) = q(\bar{b}, v_I),$$

with $p' > 0$, $q_\bar{b} \geq 0$ if $\Lambda_1 - (1 - \beta) \geq 0$, and $q_{v_I} < 0$.

Function $p(\bar{b})$ is a parabola with a minimum at $\bar{b} = 0$, whereas function $q(\bar{b}, v_I)$ is linear in $\bar{b}$ and has an ambiguous slope; it also intersects the horizontal axis at a positive value of $\bar{b}$, as long as $v_I$ is strictly positive. Both curves are shown in Figure 3 and alternative outcomes illustrated. It is immediately obvious that if $\Lambda_1 - (1 - \beta) < 0$—a condition that is more likely to occur if $v_I$ is high—there cannot be an equilibrium where $p(\bar{b}) = q(\bar{b}, v_I)$. If $\Lambda_1 - (1 - \beta) > 0$, $q(\bar{b}, v_I)$ is positively sloped and all three cases illustrated in Figure 1 may occur; there may be no equilibrium, a single equilibrium (Point $A$), or two equilibria (Points $B$ and $B'$). For two (nontrivial) equilibria to emerge, $v_I$ must be smaller than the value that it takes at Point $A$, to ensure that $\Lambda_1 = \sigma(1 - \tau)\beta - \Lambda_2$ is larger and $q(\bar{b}, v_I)$ steeper. Thus, $q(\bar{b}, v_I)$ rotates counterclockwise and shifts up at the same time. By implication, there can be neither a single equilibrium nor multiple equilibria if the investment program calls for a value of $v_I$ that is too high, because a higher value of $v_I$ shifts $q(\bar{b}, v_I)$ downward and makes it flatter, whereas it has no effect on $p(\bar{b})$.

Thus, the results with a golden rule are consistent with those obtained in studies that analyze the dynamics of public debt in endogenous growth models without public capital (such as Futagami and Shibata (2003) and Brauninger (2005)) and with public capital (such as Futagami et al. (2008) and Yakita (2008)): the low-debt steady state is characterized by high growth, and conversely for the high-debt equilibrium. Even though in the present setting government debt has a crowding-in effect as well, it is not large enough to offset the crowding-out effect on private savings and capital accumulation.

---

that the initial position of the economy puts it on a convergent path toward the high-growth, low-debt equilibrium. These results may be a good illustration of Greece’s recent predicament.
However, even though the growth rate and the public debt-private capital ratio are inversely related—not only in the steady state, but during the transition as well, as implied by (25)—public debt itself is endogenous. As a result, an increase in the share of investment $\nu_I$, in particular, has in general an ambiguous effect on growth. On the one hand, it raises the debt-private capital ratio, which tends to lower growth. On the other, it raises the public-private capital ratio, both directly and indirectly, as implied by (27). By implication, as can be inferred from (28), the steady-state growth rate of output may increase following a rise in $\nu_I$ if $\alpha$, the elasticity of output with respect to public capital, is sufficiently high.

This result can be illustrated graphically by extending Figure 1 to represent the downward-sloping curve linking $1 + \gamma_{t+1}$ and $b_t$ (equation (25)) in an additional quadrant, as in Figure 4. This curve, denoted $\Xi(b_t)$ in the figure, has a concave shape. Suppose that the initial position of the economy is at Point $B$. An increase in $\nu_I$ shifts the transition curve for $b_t$ (which does not depend on $\alpha$) upward in the upper quadrant, and raises the low steady-state value of that variable, from $B$ to $C$. Curve $\Xi(b_t)$ shifts upward in the lower quadrant, so initially growth unambiguously increases; however, as $b_t$ starts increasing towards its new, higher equilibrium value, the crowding-out effect creates a downward movement along $\Xi(b_t)$. Whether the end result is a higher or lower growth rate cannot be ascertained a priori and depends on $\alpha$. If $\alpha$ is high, the economy will move from $D'$ to $D''$ where the growth rate is higher than initially. By contrast, if $\alpha$ is low, the economy may end up at $D''$, where growth is lower than at Point $D$.

This analysis brings out another important point. Inspection of the threshold values of the investment share under the primary balance and golden rules shows that neither one of these values depends on $\alpha$. This differs from most contributions in the literature based on representative agent and OLG models, such as Futagami et al. (2008) and

\[27\] If the economy is initially at $B'$ (the high-debt equilibrium), it cannot converge to a new equilibrium, given the movement of the transition curve in this experiment.

\[28\] Of course, if the increase in $\nu_I$ is financed by a cut in unproductive spending (such that $d\nu_I + d\nu_I = 0$), the adverse effect on the debt-private capital ratio vanishes and the increase in $\nu_I$ would have an unambiguously positive effect on growth. However, as long as public borrowing is used to finance investment at least in part, the ambiguity highlighted in the foregoing discussion will continue to hold.
Yakita (2008), where that elasticity is set equal, in standard Barro (1990) fashion, to the labor elasticity of output. Put differently, the magnitude of the elasticity of output with respect to public capital plays no role in whether multiple equilibria may emerge (it does not affect the slope of the transition curve), and, as long as it is less than unity, in whether the growth rate of output and the debt-private capital ratio are positively or negatively related in the steady state.\(^\text{29}\) However, as the above experiment illustrates, it matters significantly when it comes to assessing the growth effect of a change in investment spending on infrastructure.

4 Extensions

We now consider three extensions of the basic framework: an endogenous risk premium on government debt, an endogenous primary surplus rule, a a more general golden rule in which only a fraction of public investment and interest payments are financed by debt accumulation, and network externalities associated with public capital in the production technology.

4.1 Endogenous Risk Premium

In practice, the interest rate on public debt often includes a premium that increases with net liabilities due the higher (perceived) default risk.\(^\text{30}\) Suppose now that there is indeed an endogenous risk of default, with a repayment probability \(p_t \leq 1\). If the government defaults, a bond holder receives no income. Thus, the no arbitrage condition is now \(p(1 + i_t) + 0 \cdot (1 - p_t) = 1 + r_t\), or equivalently

\[
1 + i_t = \frac{1 + r_t}{p_t},
\]

where \(p_t^{-1}\) can equivalently be defined as the risk premium.

\(^{29}\)As can be inferred from (8), in the particular case where \(\alpha = 1\) for instance, \(Y_t = K_t^I\) and the crowding-out effect of public debt disappears; in that case, the debt-private capital ratio and output growth are positively related. The same result would hold with \(\alpha > 1\). As noted earlier, however much of the (linear) empirical evidence suggests that \(\alpha < 1\)—except for the case of network externalities, which is discussed later.

\(^{30}\)For instance, the National Commission in Fiscal Responsibility and Reform (2010, p. 11) notes that “...if our national debt grows higher, the federal government may... have difficulty borrowing funds at an affordable interest rate.”
Suppose also that the repayment probability is decreasing in the debt-private capital ratio:

\[ p_t = p(b_t), \]

where \( p' < 0 \) and \( p'' < 0 \), and \( \lim_{b_t \to 0} p_t = 1 \). Thus, the higher the debt-private capital ratio, the higher the risk premium demanded by markets for holding government debt. To fix ideas, we will assume that \( p_t = b_t^{-\theta}, \) where \( \theta \geq 1 \).

Using (31), it can be shown that (21), (24) and (25) are now replaced by

\[ k_{t+1}^I = \frac{v_I \tau \beta}{\Lambda_1 - (1 - \beta)b_t^{1+\theta}}, \]

\[ b_{t+1} = \Gamma(b_t) = \frac{(1 - \beta)b_t^{1+\theta} - \Lambda_2}{\Lambda_1 - (1 - \beta)b_t^{1+\theta}}, \]

\[ 1 + \gamma_{t+1} = (v_I \tau \beta)^{\alpha} \left[ \Lambda_1 - (1 - \beta)b_t^{1+\theta} \right]^{1-\alpha}. \]

As before, the system is recursive in \( b_t \), and equation (33) can be solved for a given value of \( \theta \). Now, consider the golden rule, for which \( \Lambda_2 < 0 \), and assume that the condition \( \Lambda_1 > 0 \) (which ensures that the steady-state debt-private capital ratio is positive) holds. The following result can then be established:

**Proposition 4.** Under the golden rule, the higher the sensitivity of the risk premium to the debt-private capital ratio, the more likely it is that multiple equilibria will emerge if the steady-state value of that ratio is less than unity, and the more likely that no equilibrium will exist if that ratio is higher than unity.

In order to see this, note first that the transition curve \( \Gamma(b_t) \) is again an increasing, convex function of \( b_t \). Equilibrium occurs when \( \Gamma(b_t) \) is equal to \( b_t \), or in other words when \( \Gamma(b_t) \) intersects the 45-degree line in Figure 1. For \( \tilde{b} < 1 \), an increase in \( \theta \) reduces \((1 - \beta)\tilde{b}^{1+\theta}\), which in turn reduces \( \Gamma(\tilde{b}) \) and shifts the transition curve down, therefore making the possibility of multiple equilibria more likely. By contrast, for \( \tilde{b} > 1 \) (the case of highly-indebted countries), there may be no equilibria, as a higher \( \theta \) shifts the transition curve upward.

It can be observed that, in the particular case where \( \theta = 1 \), equation (33) yields a cubic equation in \( \tilde{b} \):

\[ (1 - \beta)\tilde{b}^3 + (1 - \beta)\tilde{b}^2 - \Lambda_1\tilde{b} - \Lambda_2 = 0. \]
With $\Lambda_1 > 0$ and $\Lambda_2 < 0$, this equation has at most two admissible (that is, positive) solutions, as in the basic framework. However, the threshold value of the investment share cannot be derived analytically. From (34), it can also be seen that, regardless of the value of $\theta$, the negative relationship between $\tilde{b}$ and the growth rate continues to hold.

4.2 Endogenous Primary Surplus Rule

In the foregoing discussion, the primary surplus rule that was considered assumed simply that the shares of spending sum up to a value lower than unity. Suppose instead that the rule involves a positive (and linear, for simplicity) relationship between the primary surplus and the debt ratio:

$$1 - (v_G + v_U) = \zeta b_t,$$

where $\zeta > 0$. This relationship, of course, holds only for $v_G + v_U < 1$. Using this specification, it can readily be established that the following dynamic system obtains:

$$b_{t+1} = \frac{\Theta_2 b_t}{\Theta_1 - \Theta_2 b_t}, \quad k_{t+1}^f = \frac{v_I \beta}{\Theta_1 - \Theta_2 b_t},$$

where $\Theta_1 = \sigma [(1-\tau) + v_U \tau \chi] \beta > 0$ and $\Theta_2 = (1 - \beta) - \zeta \tau \beta \leq 0$. As before, the system is recursive. The steady-state solution yields

$$\tilde{b} = \frac{\Theta_2}{\Theta_2 - 1}, \quad \tilde{k}^f = \frac{v_I \beta}{\Theta_2}.$$ 

For these solutions to be admissible, the coefficient $\zeta$ must be small enough to ensure that $\Theta_2 > 0$. But once again there are no multiple equilibria. However, the key difference with the exogenous primary surplus rule is that now the trivial equilibrium $\tilde{b} = 0$ is admissible; if the economy starts from a position with no debt ($b_0 = 0$), it will stay there. Any other equilibrium point with positive debt is feasible but also unstable.

---

31 This, again, is a direct implication of Descartes’ rule of signs.

32 It could be assumed alternatively that the risk premium is a function of the debt-public capital ratio (an indicator of the government’s net worth) or the debt-output ratio (a common market indicator in practice). It can be verified that in either case the dynamic system is no longer recursive. For instance, with $p_t = (B_t/K_t^f)^{-\theta}$, where $\theta \geq 1$, the transition function for $b_{t+1}$ is $[(1-\beta)(k_t^f)^{-\theta} b_t^{1+\theta} - \Lambda_2]/(\Lambda_1 - (1-\beta)(k_t^f)^{-\theta} b_t^{1+\theta})$, which depends on both $b_t$ and $k_t^f$. A similar equation holds for $k_{t+1}^f$. This system must be studied numerically.

33 As for the risk premium considered earlier, the primary surplus rule in (35) could be specified in
4.3 Generalized Golden Rule

Consider now a flexible golden rule that involves financing a fraction $\omega \in (0, 1)$ of public investment, and a fraction $\zeta \in (0, 1)$ of interest payments, through bond financing. The government flow budget constraint and the debt accumulation equation take now the form

$$
G_t^U + (1 - \omega)G_t^I + (1 - \zeta)(1 + i_t)B_t = \tau w_t,
$$

$$
B_{t+1} = \zeta(1 + i_t)B_t + \omega G_t^I,
$$

(36) \quad (37)

A fiscal policy rule therefore involves setting two additional parameters, $\omega$ and $\zeta$.

To ensure that (36) holds, one of the terms on the left-hand side must be determined endogenously. We assume that it is $G_t^U$, or more precisely the share of unproductive spending. Using (6), (8) (10), and (15) yields

$$
v_U(t) = 1 - (1 - \omega)v_I - (\tau \beta)^{-1}(1 - \zeta)(1 - \beta)b_t,
$$

which implies a negative relationship between the debt-private capital ratio and the share of spending on unproductive services. There is therefore a negative feedback effect of debt on government outlays. To ensure that (36) holds, one of the terms on the left-hand side must be determined endogenously. We assume that it is $G_t^U$, or more precisely the share of unproductive spending. Using (6), (8) (10), and (15) yields

$$
k_{t+1} = \frac{v_I \tau \beta}{\Lambda_5 - \Lambda_6 b_t},
$$

terms of the debt-output ratio or the debt-public capital ratio. In either case the system is no longer recursive, but a single equilibrium emerges once again for a wide range of plausible parameter values. These results are available upon request.

34 This is similar in spirit to Greiner (2007), where the ratio of the primary surplus to gross domestic income is a positive linear function of the debt-income ratio. This ensures that public debt is sustainable. The reasoning behind this argument is that if a government raises the primary surplus as public debt increases it takes corrective actions which stabilize the debt ratio. This implies that the debt ratio displays mean reversion and thus that it remains bounded. However, in Greiner's analysis, it is public investment that is determined residually.

35 Note that this feedback effect on private savings is related to the fact that we assumed that transfers to households are a fixed fraction of unproductive spending. If $x_t$ instead had been modeled directly as a fraction of revenues, debt would have no direct effect on private savings.
where

\[ \Lambda_3 = 1 - (1 - \omega)v_I > 0, \]
\[ \Lambda_4 = (\tau \beta)^{-1}(1 - \zeta)(1 - \beta) > 0, \]
\[ \Lambda_5 = \{\sigma[(1 - \tau) + \Lambda_3 \tau \chi] - \omega v_I \tau \beta\}, \]
\[ \Lambda_6 = \Lambda_4 \tau \chi + \zeta(1 - \beta) > 0. \]

The golden rule is no longer defined as \( v_U = 1, \) as long as \( \zeta \) or \( \omega \) is less than unity (see (38)); it now also depends on the specified values of \( \zeta \) and \( \omega. \)\(^{36}\) It is easy to show that, under that rule,

\[ b_{t+1} = \frac{\zeta(1 - \beta)b_t + \omega v_I \tau \beta}{\Lambda_5 - \Lambda_6 b_t}, \]

The basic framework of course corresponds to \( \zeta = \omega = 1, \) whereas the conventional (interest exclusive) definition of the golden rule corresponds to \( \zeta = 0 \) and \( \omega = 1. \) The important point, however, is that with \( \zeta < 1, \) the shape of the transition curve is not affected; for instance, with \( \zeta = 0, \) and with \( \omega = 1 \) as well for simplicity, we have

\[ b_{t+1} = \frac{\frac{v_I \tau \beta}{\Lambda_1 - \beta^{-1}(1 - \beta)\chi b_t}}, \]

which has a convex shape. The same result holds for \( 0 < \zeta < 1. \) Thus, the qualitative predictions of our benchmark model remain the same.\(^{37}\)

The equilibrium is now the solution to the quadratic equation

\[ \Lambda_6 \tilde{b}^2 - [\Lambda_5 - \zeta(1 - \beta)]\tilde{b} - \omega v_I \tau \beta = 0. \quad (39) \]

As before, the nature of the equilibria depends on the sign of \( \Lambda_5 - \zeta(1 - \beta). \) If \( \Lambda_5 - \zeta(1 - \beta) > 0, \) equation (39) can yield zero, one, or two positive solutions for \( \tilde{b}. \) With \( \Lambda_5 - \zeta(1 - \beta) < 0, \) there are no positive solutions to (39). The condition for \( \Lambda_5 - \zeta(1 - \beta) > 0 \) is now

\[ v_I < v_I^{GGR} = [\omega \tau + \sigma(1 - \omega)\tau \chi]^{-1}\left\{\sigma[(1 - \tau) + \tau \chi] - \frac{\zeta(1 - \beta)}{\beta}\right\}. \]

\(^{36}\)More generally, this implies that Definition 3 should be adjusted accordingly.

\(^{37}\)A primary balance rule is now defined as \( (1 - \omega)v_I + v_U = 1; \) for (38) to hold continuously, \( \zeta \) must be equal to unity, as before.
Again, \( v_I < \nu_I^{GGR} \) is a necessary condition for (39) to have an admissible solution, but it is not sufficient. In order to rule out the possibility of negative values for \( \tilde{b} \), a second condition is needed, which can be expressed as \([\Lambda_5 - \zeta(1 - \beta)]^2 - 4\Lambda_6\omega v_I\tau\beta > 0\) or, equivalently, \( \Lambda_5 - \zeta(1 - \beta) > 2\sqrt{\Lambda_6\omega v_I\tau\beta} \). Just as in the benchmark model, an analytical solution cannot be provided.

To illustrate the implications of having both \( \zeta \) and \( \omega \) less than unity we report some numerical results in Figures 5 and 6, for values of \( \beta = 0.7, \tau = 0.25, \) and \( \sigma = 0.25 \).38 The critical values for \( v_I \) in the figures yield a single equilibrium for the system, as well as being the threshold values for the existence of equilibrium. Above these critical values, there is no equilibrium whereas below these values, there are multiple equilibria.

Figure 5 displays the critical values for \( v_I \) on the vertical axis, which are by definition between zero and one, where \( \chi = 0.1, \zeta \) and \( \omega \) are shown on the \( x \)-axis and \( y \)-axis, respectively, and they vary between 0.1 and 0.5. For the parameters given above, there is no positive value of \( v_I \) that yields an equilibrium beyond the values of 0.5 for \( \zeta \) and \( \omega \), therefore these cases are omitted. The figures clearly show that as \( \zeta \) and \( \omega \) increase, which means less (more) of interest payments or infrastructure spending are being financed by tax revenues (borrowing), the government can spend less (more) on infrastructure as a fraction of tax revenues, and hence the critical value for \( v_I \) falls.

Moreover, the critical values for \( v_I \) are more sensitive to changes in \( \zeta \) than \( \omega \), as can be seen from the figure. At really low values of \( \zeta \) and \( \omega \) (when a very large fraction of interest payments and infrastructure spending are financed by tax revenues), the condition is not binding, as the critical value for \( v_I \) exceeds one in that case—and is therefore not feasible.

In Figure 6, \( \zeta \) is set at 0.25, and \( \omega \) and \( \chi \) are varied again between 0.1 and 0.5 in order to analyze the effect of the share of transfers in unproductive spending on the critical value of \( v_I \). As before, \( \omega \) is shown on the \( y \)-axis whereas \( \chi \) is on the \( x \)-axis this time. The figure shows that an increase in the share of transfers in unproductive government spending reduces the critical value of \( v_I \) as well. However, this effect is

38 The value of \( \beta \) is consistent with standard empirical estimates of the labor elasticity of output. The value of the tax rate is in the range of values used for the United States (see for instance Turnovsky (2004)). The estimate of \( \sigma \) is based on an annual discount rate of 0.04. Assuming that a period in this OLG framework is 35 years yields \( \sigma = [1/(1 + 0.04)]^{35} = 0.253 \).
much smaller than an increase in \( \zeta \), as can be seen by comparing the two figures.

Note also that, again, the earlier result of a negative steady-state relationship between the debt ratio and the growth rate continues to hold, regardless of the values of \( \omega, \chi \) and \( \zeta \).

### 4.4 Network Externalities

Suppose now that public capital is subject to network externalities, which induce non-linearities in its productivity. Until the network is built, public capital has a relatively low (and constant) marginal productivity. Once the basic parts of a network are established, and a critical mass has been reached (say, \( k^I_{m} \)), strong gains are associated with small additional increases in infrastructure investment. Beyond that (say, \( k^I_{M} > k^I_{m} \)), the marginal productivity gains induced by additional investments tend to slow down. This can be captured by assuming that the degree of efficiency of infrastructure is non-linearly related to the (congestion-adjusted) stock of public capital itself.\(^{39}\)

The aggregate production function therefore takes the form, instead of (8),

\[
Y_t = [f(k^I_t)k^I_t]^{\alpha} K^P_t, \tag{40}
\]

where \( f(0) = 1, f' > 0, \) and \( f'' > 0 \) for \( k^I_t \leq k^I_{m} \), and \( f'' < 0 \) for \( k^I_t \in (k^I_{m}, k^I_{M}) \). To fix ideas, we set \( f(k^I_t) = (k^I_t)^{\varepsilon} \), where \( \varepsilon > 1 \) over the range \( k^I_t \in (0, k^I_{m}) \). Thus, network effects take a convex form.

It is straightforward to show that the steady-state solutions (26) and (27) for \( b_t \) and \( k^I_t \) remain the same (which implies, in particular, that neither \( \alpha \) nor \( \varepsilon \) affects the threshold values of \( v_I \) in the basic framework), whereas (28) is replaced by

\[
1 + \gamma = (v_I \tau \beta)^{\varepsilon(1+\varepsilon)|\Lambda_1 - (1 - \beta)\tilde{b}|^{1-\alpha(1+\varepsilon)}].
\]

Based on this solution, and the results of the previous section, the following proposition can be established.

**Proposition 5.** If network externalities are sufficiently strong \( (\varepsilon > \alpha^{-1} - 1) \), a low (high) debt equilibrium under the golden rule is associated with a low (high) steady-state growth rate of output.

---

\(^{39}\)See for instance Agénor (2010). Evidence of threshold effects in the relationship between output growth and infrastructure is provided by Röller and Waverman (2001), Égert et al. (2009), Roberts and Deichmann (2009), Czernich et al. (2011), and Candelon et al. (2014).
Thus, the steady-state growth rate of output may now be positively related to the debt-private capital ratio. Intuitively, this result holds because with network externalities, and with the marginal product of private capital depending positively on the available stock of public capital, the crowding-in effect is stronger—at least up to a certain level of the public-private capital ratio. In addition, the effect of a shift in the share of spending on investment on growth is now magnified.

However, with \( \varepsilon \) high enough, the high-debt, high-growth equilibrium (Point \( B' \) in Figure 1) remains unstable; unless the economy starts there, it cannot be reached over time. Suppose instead that the initial equilibrium is at Point \( B \), which (again, with \( \varepsilon \) high enough) is now a low-debt, low-growth equilibrium. Because, as shown earlier, this equilibrium exists only when \( v_I < v_C^2 \vert_{v_U=1} \), an increase in the share of investment to exactly \( v_C^2 \vert_{v_U=1} \) will shift the economy from Point \( B \) to Point \( A \), an equilibrium characterized by higher growth and a higher debt-private capital ratio.

An obvious question, of course, is whether Point \( B \) is preferable to Point \( A \) (or any point located to the Northeast of \( B \), corresponding to a higher \( v_I \)), from a welfare point of view. Intuitively, the output growth effect, which is positive, is likely to be welfare-improving. At the same time, however, higher debt means a higher burden on future generations, and this may be welfare reducing. In general, therefore, whether an equilibrium with higher debt and higher growth is preferable to an equilibrium with low debt and low growth (such as Point \( B \)) from a welfare standpoint is likely to be ambiguous. This result is formally established in the Appendix, where the welfare analysis is restricted to the balanced growth path. However, as also shown in the Appendix, the stronger the network externality, the more likely it is that the net welfare effect will be positive, reflecting the strength of the growth effect. In addition, the condition established in Proposition 5 is sufficient, although not necessary, for the welfare effect to be unambiguously positive.40

These simple results have important practical implications for industrial countries.

---

40 Adding a utility benefit to public capital (improved access to faster transportation may enhance leisure, for instance) implies that the net welfare gain would be more likely to be positive. Doing so would not affect the derivations provided earlier, as long as it is introduced additively in the household utility function. Conversely, however, if unproductive spending \( G_U^U \) were to affect utility, under a generalized golden rule an increase in \( v_I \) would lower \( v_U \) (as implied by \( (38) \)), and the change in welfare would be ambiguous. 29
and for those developing countries where market-based bond financing of public deficits is a viable option. For the latter group of countries, where stocks of infrastructure are relatively low to begin with, there is strong evidence to suggest that network effects associated with additional investment are likely to be strong across a broad range of infrastructure assets. For industrial countries, even though these externalities in “basic” infrastructure such as roads and telecommunications may have long been exhausted, there are certain types of infrastructure for which they are likely to remain powerful—in particular, high-speed rail, air-traffic control systems, and high-speed broadband.41 In Europe, a report by ESPON (2009), the European Observation Network for Territorial Development and Cohesion, concluded that high-speed rail lines had a significant impact on “accessibility,” defined as a key determinant of the potential for activities and firms in a particular region to reach markets and activities in other regions. In the case of broadband, studies by the European Union have shown that the replacement of aging copper networks with next-generation optic fiber networks could have a substantial impact on growth.42

As noted in the introduction, the United States is considering massive investment programs in these areas. In the United Kingdom, similar investments are also envisaged in the context of a National Infrastructure Plan.43 Even though sustainability considerations may impose limits on all types of spending, this result illustrates the importance of preserving, even in a context of fiscal retrenchment, the allocation of resources to specific types of public investment—those with potentially strong externalities with respect to private production. In fact, externalities associated with infrastructure may

---

41From the perspective of many industrial countries, the issue with “basic” infrastructure may not be to invest more (increase supply) but rather to manage demand better so as to optimize the use of existing assets. This is the case for instance for clogged highways: rather than adding new lanes, measures could involve improving computerized traffic management to steer drivers away from jams, encouraging telecommuting, carpooling and mass transit to take cars off the road, freight-rail improvements to take trucks off the road, zoning changes to allow denser housing near job centers and tran stations, etc. Similarly, for electricity grids, the issue may often be better management of demand, through more efficient computerized systems, peak-load pricing, etc.

42In principle, to account for the possibility that network externalities may exist only for a certain category of infrastructure assets, we should introduce two types of infrastructure in the model. However, this would only complicate the analysis without adding any insight.

43According to some recent estimates, high-speed rail could lead to the creation of a million new jobs and boost GDP in the Midlands and the North of the country by 3 percent.
exist not only with respect to its impact on the production of goods, but also (as is the case for broadband, for instance) for the production of human capital and the capacity to innovate—both of which likely to promote growth.44

5 Concluding Remarks

The purpose of this paper was to analyze the dynamics of public debt in a simple two-period overlapping generations model of endogenous growth with productive public goods. Considering first a basic framework, alternative fiscal rules were defined, including a golden rule whereby investment in infrastructure, and interest payments on public debt, were financed by issuing bonds. Conditions under which a single equilibrium and multiple equilibria may emerge were characterized. It was also shown that the steady-state relationship between output growth and the debt-private capital ratio is unambiguously negative under the golden rule, implying that, with multiple equilibria, the low- (high-) debt equilibrium is associated with a higher (lower) growth rate. Intuitively, an increase in the share of public spending on investment has two opposite effects on fiscal sustainability. On the one hand, it raises the public capital stock, improves productivity of private inputs, and raises the accumulation of private capital, thereby promoting the rate of economic growth. On the other, it results in higher interest rates and leads to more public debt accumulation. This has a negative impact on fiscal sustainability due to the crowding-out of private capital, and this hampers growth. However, even though the growth rate and the public debt-private capital ratio are inversely related in the steady state, it was shown that an increase in the share of investment in infrastructure has an ambiguous effect on long-run growth: on the one hand, it raises the debt-private capital ratio, which tends to lower growth; on the other, it raises the public-private capital ratio, both directly and indirectly. If the elasticity of output with respect to public capital is sufficiently high, the steady-state growth rate of output will increase. This result was established because, unlike previous studies, a proper distinction was made between the elasticities of output with respect to labor and public capital.

44See Agénor and Neanidis (2010) for a discussion and empirical evidence.
The analysis was then extended to consider the case of an endogenous risk premium, an endogenous primary surplus rule, a generalized golden rule, and network externalities. With an endogenous risk premium, the higher the sensitivity of that premium to the debt-private capital ratio, the more likely it is that multiple equilibria will emerge if the steady-state value of that ratio is less than unity; by contrast, if the debt-private capital ratio is too high, it is more likely that there may be no equilibria. With the generalized golden rule, the crowding-out effect on private capital formation associated with public debt accumulation is magnified, as a result of a direct effect on transfers and household savings. The higher the proportion of interest payments financed by tax revenues, the higher is the (sustainable) share of these revenues that the government can spend on infrastructure—despite the fact that this increase lowers the share of other spending, including transfers, and thus private savings and investment. With network externalities, the qualitative features of the dynamics of the debt-private capital ratio do not change, but a steady-state characterized by high growth and high public debt can now emerge if network effects are sufficiently strong. This is in contrast to the inverse steady-state relationship between output growth and the debt-private capital ratio obtained in the basic framework and the rest of the literature. A large enough increase in the share of output allocated to public investment may shift the economy from a low-growth, low-debt equilibrium to an equilibrium characterized by both higher debt and higher growth. This shift may be welfare-enhancing as well, particularly so if in addition to its productivity effects public capital generates some utility benefits.

Despite the simplicity of the model, these results have important implications for the current debate on fiscal consolidation and growth, especially in industrial countries. Even though network externalities may have long been exhausted for many types of “basic” infrastructure assets, they are likely to remain strong for some specific types, such as high speed rail and broadband. And if indeed these effects are strong, the analysis in this paper illustrates the importance of preserving, even in a context of fiscal consolidation, a sufficient level of public investment. A well-designed fiscal adjustment program can both promote growth and ensure fiscal sustainability in the long run.

The analysis can be extended in several directions. First, alternative fiscal rules
can be studied, along the lines of Turnovsky (1997), Bohn (1998), Buiter (2004), An-" 

nichiarico and Giammarisi (2008), Futagami et al. (2008), Fernandez-Huertas and 

Vidal (2010), and Michel et al. (2010), who consider endogenous responses of both 

spending (especially unproductive outlays) and tax rates to deviations in the debt- 

output ratio. A broader focus on different ways of financing productive government 

spending, would indeed help to shed light on some of the policy options that govern- 

ments often face in practice.45 In the present case, if the tax rate increases sufficiently 

rapidly with the debt-output ratio (or deviations in that ratio from its steady-state 

value), as in a “spend and tax” approach, the transition curve $\Phi(b_t)$ in (24) may turn 

concave—ensuring therefore a stable, single long-run equilibrium. Alternatively, it 

could be assumed that interest income of the old is also taxed, and that the tax rate on 

that category of income rises with the gap between the actual debt-output ratio and 

a target level. This would capture the idea that high-income earners may need to be 

taxed at a higher rate to ensure fiscal sustainability. Such feedback rules may be part 

of balanced-budget rules, which are the most common in practice.46 Intuitively, it is 

likely that with feedback rules of this type stability will depend critically on what the 

target level of the debt-output ratio is. However, the possibility of multiple equilibria 

(some of them unstable) will also remain.

Second, it would be useful to study in our setting the stability implications of 

public-private partnerships in the provision of infrastructure services. In particular, 

instead of assuming responsibility for full financing of investment projects, it could 

be beneficial for the government to remain involved only in cofinancing investment 

activities that would otherwise not be carried out by the private sector and that are 

deemed to be socially profitable.47 This, of course, does not mean that governments

---

45 In this context, political economy considerations focusing on conflicts between young and old 
on ways to finance productive spending may be important. See Song et al. (2012) and Lancia and 
Russo (2013). In the latter paper for instance, the middle aged support productive investment today 
(education, even though they do not benefit from it directly) because they want to ensure that the 
tax base is sufficiently large next period when they are old to finance transfers.

46 A good example is the pay-as-you-go rule implemented in the United States during the 1990s. 
Before it expired in 2002, the rule forced Congress to pay for tax and entitlement-spending changes 
with offsetting budget fixes, so that any new measure would be deficit-neutral over 5 and 10 years.

47 The National Infrastructure Plan 2010 of the UK Government (especially in the areas of energy 
and broadband) is assumed to be financed in part through public-private partnerships.
should not invest, but that they should do so selectively, complementing private capital formation. To the extent that these partnerships reduce costs or provide additional fiscal revenues (despite the lower future stream of resources diverted to the private sector), and that these revenues are used in part to finance on-balance sheet investment, fiscal sustainability would be enhanced. However, key issues in this context remain the extent of risk transfer (in the form of implicit liabilities) between the private and public sectors, and the need to ensure that private operators internalize the social benefits that public capital externalities may generate.

Finally, much of the emphasis in the model has been on the productivity effects of public capital. However, there are a number of other channels through which infrastructure (or at least particular types of it) may affect growth. In particular, access to broadband infrastructure is critical for generating and distributing information and ideas, which in turn are important steps to promote innovation (Czernich et al. (2011)). By helping to promote access to learning material and distance education, broadband networks may also help to foster human capital accumulation and the quality of the labor force. Accounting for these externalities and their growth effects—perhaps in a context where distortive taxation also affects labor supply—may provide further reasons as to why maintaining a core program of public investment is important even in times of fiscal consolidation.
Appendix

This Appendix examines the effect of an increase in the infrastructure spending share on welfare, along the balanced growth path. In standard fashion, assume that the government’s welfare function is a discounted sum of the utility of the representative individual of the present and all future generations, \( W_t = \sum_{t=0}^{\infty} \xi^t U_t \), where \( \xi \in (0, 1) \) is a constant discount factor which reflects social time preferences and may differ from each individual’s subjective discount factor.

From (1), the utility function can be written as

\[
U_t = \ln c_t^l + \Sigma_1 \ln \tilde{c}_{t+1}^l, \tag{A1}
\]

where \( \Sigma_1 = 1/(1 + \rho) \). From (2), (6), and (14), \( c_t^l \) can be written as

\[
c_t^l = \Sigma_2 Y_t, \tag{A2}
\]

where

\[
\Sigma_2 = (1 - \sigma)[(1 - \tau) + \upsilon_{t+1}] \beta.
\]

Similarly, from (3), (6), (8), and (14) yields

\[
c_{t+1}^l = \Sigma_3 (\tilde{k}_{t+1}^l)^{\alpha} Y_t, \tag{A3}
\]

where

\[
\Sigma_3 = \sigma(1 - \beta)[(1 - \tau) + \upsilon_{t+1}] \beta.
\]

Substituting (A2) and (A3) in (A1) implies that the representative individual’s lifetime utility is

\[
U_t = \Sigma_4 + (1 + \Sigma_1) \ln Y_t + \alpha \Sigma_1 \ln \tilde{k}_{t+1}^l,
\]

where

\[
\Sigma_4 = \ln \Sigma_2 + \Sigma_1 \ln \Sigma_3.
\]

Along the balanced growth path, the public-private capital stock is constant at \( \tilde{k}^l \), as shown in the text. The above expression becomes

\[
\tilde{U}_t = \Sigma_4 + (1 + \Sigma_1) \ln \tilde{Y}_t + \alpha \Sigma_1 \ln \tilde{k}^l.
\]

In addition, along the steady-state equilibrium path, \( \tilde{Y}_t = Y_0(1 + \gamma)^t \). Substituting this result in the above expression yields

\[
\tilde{U}_t = \Sigma_5 + (1 + \Sigma_1)t \ln(1 + \gamma) + \alpha \Sigma_1 \ln \tilde{k}^l, \tag{A4}
\]

where

\[
\Sigma_5 = \Sigma_4 + (1 + \Sigma_1) \ln Y_0.
\]
This expression implies that welfare is increasing in the growth rate $1 + \gamma$, given in (28), and depends on time. From (27) and (28),
\[ 1 + \gamma = (\tilde{k}^t)^\alpha [\Lambda_1 - (1 - \beta)\tilde{b}]. \]

Substituting this expression in (A4) yields
\[ \tilde{U}_t = \Sigma_5 + \alpha [(1 + \Sigma_1)t + \Sigma_1] \ln \tilde{k}^t + (1 + \Sigma_1)t \ln [\Lambda_1 - (1 - \beta)\tilde{b}]. \quad \text{(A5)} \]

Equation (27) can be rewritten as $[\Lambda_1 - (1 - \beta)\tilde{b}] = \tilde{\nu}_t \beta (\tilde{k}^t)^{-1}$. Substituting this result again in (A5) yields now
\[ \tilde{U}_t = \Sigma_5 + [(\alpha - 1)(1 + \Sigma_1)t + \alpha \Sigma_1] \ln \tilde{k}^t + (1 + \Sigma_1)t \ln \nu_t \beta. \quad \text{(A6)} \]

Consider first the case where $t \to 0$. Expression (A6) boils down to
\[ \tilde{U}_0 = \Sigma_5 + \alpha \Sigma_1 \ln \tilde{k}^t. \]

As discussed in the text, under all the fiscal rules considered in the paper, an increase in $\nu_t$ unambiguously increases $\tilde{k}^t$. Thus, under the (interest-inclusive) golden rule, under which $\nu_U = 1$ and $d\Sigma_5/d\nu_I = 0$, investing more today increases welfare unambiguously if the government is concerned only with the welfare of the present generation. However, note that with the generalized golden rule, the condition $\nu_U = 1$ does not hold anymore, and $d\Sigma_5/d\nu_I < 0$. Thus, even if the government is concerned only with the welfare of the present generation, higher $\nu_t$ does not necessarily imply an increase in welfare.

Consider now the case where $t > 0$. Inspection of (A6) shows that an increase in $\nu_t$ raises the last term directly. Under the (interest-inclusive) golden rule, again, $d\Sigma_5/d\nu_I = 0$. In addition, an increase in $\nu_t$ (as noted earlier) increases $\tilde{k}^t$. However, whether the second term in (A6) is positive or negative depends on the sign of $(\alpha - 1)(1 + \Sigma_1)t + \alpha \Sigma_1$, and thus also on $t$. If $\alpha$ is sufficiently less than one, for $t$ given, this term can be negative. If it exceeds the third term, then the net effect on welfare can be negative. Conversely, if $\alpha$ is sufficiently high, the net welfare effect will be positive. Intuitively, the source of the ambiguity is due to the fact that the burden of debt is shifted across generations, which ensures that the “crowding out” effect perpetuates itself. Unless the growth (or “crowding in”) effect of public capital is strong, future generations are worse off as a result.

Finally, note that if there are network externalities, the term $\alpha - 1$ in (A6) would be replaced by $\alpha(1 + \varepsilon) - 1$. If so, the stronger the network externality, the more likely it is that the net welfare effect will be positive, reflecting the strength of the growth effect. In addition, $\alpha(1 + \varepsilon) > 1$ is a sufficient (although not necessary) for the welfare effect to be unambiguously positive.
